Abstract
After mitral valve replacement in an 81-year-old woman, there was evidence of an important communication between the esophagus and the right pleura. Diagnosis was confirmed with Oral Gastrografin radiography and esophagoscopy. Thoracic computed tomography scans better indicated fistula location and extension, but also showed the close relationship and the compression of huge left atrium on the esophagus. Our hypothesis was that the lesion was induced by transoesophageal echocardiography probe in a favourable setting. An enlarged left atrium should be recognized as a risk factor for TEE-induced esophageal perforation, especially in fragile patients, with marked esophagus distortion.

Index terms — esophageal fistula, pleural fistula, transoesophageal echocardiography, left atrium.

1 Esophageal-Pleural Fistula after Intraoperative Transoesophageal Echocardiography in a Patient with Enlarged Left Atrium

2 Case Presentation

An 81-year-old woman was admitted to our cardiac surgery department because of a severe dyspnoea of one month duration also at rest and an episode of acute pulmonary oedema. At the admission she had mild dyspnoea, a blood pressure of 110/70 mmHg and a long standing persistent a trial fibrillation rhythm at the electrocardiogram. Blood test were almost normal: haemoglobin 13.2 g/dl, transaminases < 20 mg/dl, creatinine 0.83 mg/dl, brain natriuretic peptide 657 pg/ml. Chest radiograph indicated a significant increase of the vascular network in both the lungs. Transthoracic echocardiography showed a normal left ventricular systolic function, with a 52% ejection fraction, a moderately dilated left ventricle (tele-diastolic volume: 89 ml/m^2), and a huge left a trial chamber (area: 48 cm^2, volume/BSA: 52 ml/m^2). At the doppler examination, a severe and symptomatic mitral valve regurgitation was diagnosed (vena contracta: 7 mm, EROA 46 mm^2, regurgitant volume: 72 ml). The aortic valve appeared to be normal and there was a minimal physiologic tricuspid regurgitation. The heart team opted for a surgical approach and then she underwent mitral valve replacement and a porcine bioprosthesis (Carpentier Edwards Perimount Magna Mitral Ease, 29 mm) was implanted. Transoesophageal echocardiography (TEE) was used in a conventional intraoperative setting (at baseline, for de-airing and surgical result evaluation) and the probe was inserted without any resistance. On the fourth postoperative day, there was evidence of a yellowish
material from the right thoracic drainage, while she was drinking. She was asymptomatic, a febrile, with modest
leucocytosis and increase of inflammatory indexes.

Suspecting the existence of an esophageal pleural fistula, Methylene blue was given orally, and it coloured the
chest tube drainage. Parenteral nutrition was started immediately. Antibiotic prophylaxis was then started and
medications were given intravenously.

Oral Gastrografin radiography confirmed a communication between the esophagus and the right pleura (Fig.
Thoracic computed tomography (CT) scans clearly indicated the fistula location (Fig. 2A) and esophagoscopy
showed a wide opening -6cm-on the right surface of the distal esophagus (Fig. 2B). No other anomalies were
found. We speculated that perforation could be due to ischemia of the esophagus resulting from the combination
of TEE probe compression and non-pulsatile flow during a lengthy on pump procedure, in a fragile patient, as it is
already well reported in the literature [1]. Moreover, in our patient, CT images clearly showed a giant left atrium
-indexed volume 52 ml/m 2compressing and displacing the oesophagus, right in the fistulated region. Several
studies reported cases of esophagus compression and distortion by enlarged left atrium related to mitral valve
disease 2: this anatomic feature should be recognized as a risk factor for TEE-related esophageal complications.

Finally, a 15 x 2 cm auto expandable esophageal stent was placed endoscopically. No residual communication
was observed, and a new CT scan confirmed the good result (Fig. 3).

Discussion

TEE is used routinely during cardiac surgery to monitor cardiac haemodynamic, weaning off cardiopulmonary
bypass, air removal, and valve function, but although it is a relatively safe exam, it may result in some
complications 3 . During cardiac surgery, the insertion, manipulation, and removal of the probe may increase
those complications 4 . Moreover, when cardiopulmonary bypass (CBP) is necessary as in this case, patient’s
temperature is lowered to 32-29° C, there is a significant inflammation reaction and the blood flow provided
has a continuous pattern, not a pulsatile one. All these conditions can cause micro-ischemia, facilitate tissue
damage and weak the oesophageal wall, even if any movement or manipulation of the probe was gentle and TEE
examination intermittently and automatically to decrease the probe temperature the risk of tissue damage. In
addition, a huge left atrium might chronically compress the anterior oesophageal wall, causing local ischemia, and
might displace it, generating dangerous bends which can make easier a TEE-mediated damage. However it has
been reported that the majority of iatrogenic esophageal damages occurs in patients with an unknown esophageal
or gastric pathology 5 .

In this case, our hypothesis was that the lesion was induced by transoesophageal echocardiography probe
in a favourable setting: huge left atrium which displaced the thoracic oesophagus, in a very frail patient who
underwent a quite long surgical procedure, using CBP with long-time perfusion with continuous blood flow.

Conclusion

TEE is a fundamental tools during cardiac surgery, however for patient safety, comprehensive intraoperative TEE
guidelines should always be followed. And an enlarged left atrium should be recognized as a main risk factor for
TEE-induced esophageal perforation, especially in fragile patients, with marked esophagus distortion.

The authors have no conflict of interest to declare and no founding.
