Musculoskeletal Complications Associated with Vitamin D Deficiency and Review of Current Interventions

By Vikramaditya Rai

Abstract - Background: Hypovitaminosis D is commonly prevalent in older population world over leading to increased levels of bone resorption, reduced bone mass, often resulting in osteoporosis and increased chances of falls and fractures. In children, vitamin D deficiency is known to cause rickets due to hypomineralization of bone.

Methods: PubMed, EMBASE, Cochrane Library and Google Scholar databases were searched from database inception until May 20, 2022. Searches were performed between January 2022 and May 2022.

Keywords: vitamin D, musculoskeletal, osteoporosis, rickets, bone fracture, bone density.

Musculoskeletal Complications Associated with Vitamin D Deficiency and Review of Current Interventions

Abstract - Background: Hypovitaminosis D is commonly prevalent in older population worldwide leading to increased levels of bone resorption, reduced bone mass, often resulting in osteoporosis and increased chances of falls and fractures. In children, vitamin D deficiency is known to cause rickets due to hypomineralization of bone.

Methods: PubMed, EMBASE, Cochrane Library and Google Scholar databases were searched from database inception until May 20, 2022. Searches were performed between January 2022 and May 2022.

Results: Although vitamin D is used for better bone health in general population, data from randomized controlled trials (RCTs) have been inconsistent. We studied whether daily vitamin D supplementation with or without calcium improves bone mineral density (BMD) and bone architecture. Supplementation with vitamin D for 3 to 5 years minimally decreased total fracture incidence, but findings were not precise. Supplementation of vitamin D with calcium for 3 to 5 years had no significant effect on total fracture incidence or hip fracture incidence in men and women. Pediatric vitamin D status is associated with avoidance of rickets. Observational studies point to at least 10µg/day vitamin D supplementation for attaining optimum bone health in children, but the results of RCTs have been unclear. However, despite 10 RCTs reported on adolescent girls, the definitive amount of vitamin D supplementation and its association with optimal bone mineralization remains ambiguous and not much is known regarding the needs of male children.

Conclusion: The available evidence from completed RCT studies provided only limited or no support for the effect of vitamin D alone on prevention of fracture. However, vitamin D supplementation combined with calcium seemed to slightly reduce the likelihood of fractures. RCTs assessing the effects of higher daily doses of vitamin D on fracture risk are needed before making recommendations on the use of vitamin D alone or in combination with calcium for the prevention of fractures in high risk individuals. Specific vitamin D supplementation to optimize the pediatric outcomes is unknown, but doses 10-15 µg/day are safe and may be beneficial.

1. Introduction

Hypovitaminosis D is widespread and represents a serious health problem globally. Approximately one billion people worldwide suffer from vitamin D deficiency and nearly 50% of world population is vitamin D insufficient [1]. It was discovered about a 100 years ago that ultra violet radiations of the sun stimulates the conversion of cholesterol into vitamin D. Being a prohormone, vitamin D plays a vital role in controlling calcium and phosphorus metabolism, and thus is essentially crucial detriment of bone health in people of all age groups. Aging is closely associated with changes in lifestyle, biological and socio-economic changes. Studies have indicated that dermal capacity to synthesize the vitamin in people after 65 years is estimated to be about 25% of that in people of ages 20-30 years on exposure to the same amount of sunlight [2]. This reduction is related to the reduction in the concentration of skin 7- dehydrocholesterol. Other secondary factors which contribute to lower concentration of vitamin D in elderly people, include decreased physical activity, reduced exposure to sun as more time is spent indoors, or increased use of sunscreen lotions [3].

The role of vitamin D as mineral supplier in normal bone and dental development is well established [4]. Calcium is absorbed from the gut when active vitamin D metabolite 1,25(OH)2D opens up calcium channels in the gut, stimulating the formation of calcium binding protein in the intestinal cells (Fig. 1). Once sufficient vitamin D and calcium are available, optimal circumstances for bone mineralization are created. However, when there is vitamin D deficiency the 1,25(OH)2D concentration drops, as a result, less calcium is available for bone mineralization (Fig. 2). The parathyroid hormone(PTH) level increases resulting in hydroxylation of 25(OH)D in the kidney to 1,25(OH)2D. Increased PTH level in turn stimulates bone turnover, leading to bone loss [5]. When there is prolonged vitamin D deficiency, bone loss is increased, thus leading to osteoporosis. Higher turnover bone means more osteoid tissue (the bone which has not yet mineralized) which causes more than normal remodeling on the bone surface. As a result, the mineralized bone contains less mineral as mineral accumulation takes place up to two years after osteon formation. In case of severe prolonged vitamin D deficiency the volume of osteoid tissue accumulates to more than 5% leading to osteomalacia. Generalized and progressive decrease of skeletal muscle mass and...
Musculoskeletal complications associated with vitamin D deficiency and review of current interventions

Strength are the major musculoskeletal consequences associated with vitamin D deficiency. Hypovitaminosis in older individuals directly interferes with changes in musculoskeletal system [6].

Figure 1: Vitamin D synthesis in the body in a normal healthy adult.
Among children, the most severe form of vitamin D associated disease is Rickets. Rickets occurs when hypocalcemia and/or hypophosphatemia affect the development of the epiphyseal growth plate and is most common in infancy. Nutritional rickets is most common in children in the Middle East, Africa, and South Asia and its prevalence is now increasing in high-income countries, largely governed by inflow of immigrant populations.

II. Purpose of Review

Osteoporosis, osteomalacia and rickets are common musculoskeletal diseases associated with vitamin D deficiency among aging global populations and children irrespective of race, region, sex, age and ethnicity. Changing population demographics, ill planned implementation strategies, and weak prevention policies are the chief hurdles in overcoming the vitamin D associated complications. This article reviews sustainable prevention strategies and identifies areas of future research.

III. Materials and Methods

We searched PubMed, EMBASE, Cochrane Library and Google Scholar databases using MeSH terms “vitamin D”, “cholecalciferol”, “osteoporosis”, “osteomalacia”, “Rickets”. Figure 2: Pathophysiologic pathways of vitamin D deficiency causing osteoporosis, osteomalacia, falls and fractures.
“ostomalacia”, “Rickets” using logical operators “AND” or “OR”. We selected observational studies and RCTs of risk of fractures and change in BMD associated with vitamin D supplementation Vs. placebo or recommended dose Vs. high dose alone or in combination with calcium. Literature search was conducted from January 2022 to May 2022. Two reviewers were involved in data acquisition, two were involved in quality assessment for their inclusion in proposed observational studies and one reviewer combined the results of earmarked studies to obtain the summary of effects.

a) Vitamin D and Osteoporosis

Global statistics indicate that more than 200 million people are currently suffering from osteoporosis [7], a metabolic bone disease with low bone density and weak musculoskeletal architecture increasing the risk of fractures due to inadequate bone mineralization and decreased bone strength [8]. With more than 8.9 million fractures per year, osteoporosis is a worldwide concern. Although osteoporosis is typically associated with post-menopausal women, it also occurs in men with low BMD [9]. One in five American males have osteoporosis or low BMD [10]. The condition often remains undiagnosed due to being asymptomatic until it exhibits a fracture of the hip, pelvis, humerus (proximal), spine or wrist requiring hospitalization [11]. In addition, elderly people can also become bedridden thus leading to serious outcomes including mortality [12].

Primary Osteoporosis: Primary osteoporosis is associated with age and sex hormone deficiency. Age related osteoporosis is the resultant of continuous deterioration trabeculae in bone. Moreover, there is a significant increase in bone loss due to the reduced production of estrogen in post-menopausal women. In men, as aging occurs, testosterone and estrogen are inactivated by sex hormone binding globulin, thereby contributing to decrease in BMD with time [10,12,13,14]

Secondary osteoporosis: Several comorbid diseases and medications cause secondary osteoporosis. This may be attributed to the imbalance in regulatory mechanisms of calcium, vitamin D and hormones [10,15]. In addition, when patients are suffering from some inflammatory diseases such as rheumatoid arthritis, they are put on long-term glucocorticoid therapy and have been associated with secondary osteoporosis [14,16]. For men, excessive use of alcohol and hypogonadism are more commonly associated with osteoporosis [17]. Whereas, osteoporosis in 32.4% women was attributed to hypercalcaemia, malabsorption of calcium, hyperparathyroidism, Cushing’s disease, and hypocalciuriahypercalcaemia [18]. However, disorders of calcium metabolism and hyperparathyroidism contributed to 78% of secondary causes [19].

b) Vitamin D and Rickets

During childhood and adolescence hypovitaminosis D is mainly attributed to poor and unbalanced diet. During the initial years of life, absence of adequate sun exposure or vitamin D supplementation is an important risk factor for vitamin D deficiency [20], while, in adolescence, fast food and junk food are the relevant risk factors. Signs and symptoms associated with rickets include bowing of legs, knock knees, rachitic rosary, muscle weakness, seizures, tetany and cardiomyopathy. Radiographic findings reveal cupping, fraying and splaying of metaphysis near the epiphyseal growth plate. Muscle weakness and muscle pain has also been described in vitamin D deficiency associated bone disease [21,22,23].

90 % of adult bone mineralization is accumulated by the end of adolescence [24]. Furthermore, vitamin D status in adolescence may be of great significance because 40% of adult bone mineralization occurs within this time of peak bone growth velocity [25].

IV. Results and Discussion

Vitamin D status is related to BMD in vitamin D deficient as well as vitamin D insufficient subjects. In this review article, several studies exploring the relationship of serum 25(OH)D and BMD have been described and analyzed. In addition, the cross sectional studies conducted to find the effect of vitamin D supplementation on bone turnover and prevention of fractures have also been discussed to affirm the effect of vitamin D supplementation on bone health in children as well as in the aging population. Some meta-analysis show that calcium should be added to vitamin D in order to be effective in reducing the risk of hip fracture [26]. Whereas, another meta-analysis of calcium supplementation studies suggested that co supplementation may increase the risk of cardiovascular disease [27].

According to one study [28], men and women between ages 50-55 years were supplemented with vitamin D3 (2000 IU/day for 2 years) without calcium, compared with placebo did not significantly benefit bone density or structure in this study. Supplemental vitamin D3 did not increase BMD or prevent bone loss at the spine, hip or whole body. It also did not improve or adversely affect total, trabecular, or cortical BMD, cortical thickness or bone strength at the radius or tibia as compared to placebo.

Another RCT study [29] consisting of 53% men and 47% women with average age of 62.2 years were administered with vitamin D for 3 years at a dose of 4000 IU/day or 10000 IU/day compared with 400 IU/day resulted in statistically significant lower radial BMD, tibial BMD was significantly lower only with 10000 IU/day dose. No significant differences were reported in bone
strength at either the radius or tibia. These findings do not support the benefit of high dose of vitamin D supplementation for bone health.

According to still another RCT conducted in England [30], three different doses of vitamin D (12000, 24000, 48000 IU/month), were tested for their effect on BMD on individuals >70 years of age for one year. No difference in BMD between three doses of vitamin D suggests no effect of the intervention. However, parathyroid hormone concentrations decreased in all three groups, with significantly greater decrease in 48000 IU group (p<0.01). The treatment was safe and effective in increasing plasma 25(OH)D concentrations with no dose related adverse effects. Further, two RCTs that assessed very high annual doses of vitamin D, both showed an increase in the rate of fractures and falls among those allocated to vitamin D group [31,32] reinforcing the conclusion that intermittent dosing regimens with high dose of vitamin D cause toxic effects.

A number of observational studies of blood 25(OH)D concentration and risk of fracture demonstrated that higher blood 25(OH)D concentrations were associated with lower risks of any fracture and hip fracture. An increase of 10.0 ng/ml in 25(OH)D concentration was associated with a 7% lower risk of any fracture and 20% lower risk of hip fracture [33]. The same comparative study of RCTs demonstrated that vitamin D and calcium demonstrated a marginally significant reduction in the risk of any fracture of 6% and hip fracture of 16%. However, 95% CIs indicated some uncertainty of these estimates. As with RCTs of vitamin D supplementation alone, this study demonstrated no beneficial association with risk of fracture. However, elucidation of the results of these RCTs is restricted by their small sample size, short treatment duration, high risk of bias (chiefly because of incomplete follow up of outcomes), fragmented dosing regimen of vitamin D, and failure to achieve adequate differences in 25(OH)D concentrations.

Randomized controlled trials of vitamin D supplementation to optimize bone health have been performed in adolescents and mostly in females. Two review studies (34, 35) by the same authors concluded that vitamin D supplementation demonstrated no significance effect on total body mineral content (BMC) or bone mineral density of hip or forearm. Another study in girls who were less than 2 years past menarche showed improvement in total body and lumbar spine BMC with vitamin D supplementation [36].

Another area of potential consequence of vitamin D deficiency in pediatric bone health is the risk for fracture. One study has examined the potential association of vitamin D deficiency and risk of fractures in children [37], while a cross-sectional study of 10 to 16 years old children, those with upper limb fracture, lower limb fracture and no fracture demonstrate no significance difference in 24(OH)D status [38]. In a case control study of 5 to 9 years old African American children, compared to 74 controls, the 76 cases exhibited 3.64 (95% CI 1.09 – 10.94) higher odds of vitamin D deficiency [39]. A study of children under 2 years of age who were admitted with fractures, 11 of 79 demonstrated hypomineralization on skeletal findings. For every 10 point increase in vitamin D status, the adjusted odds of hypomineralization were reduced 0.3 (95% CI 0.17 – 0.82) [40]. According to a recent RCT study findings, vitamin D sufficient children, at the age of 6 months, from mothers receiving high dose of vitamin D supplementation (2800 IU/day) during pregnancy had a 60% reduced incidence of fractures compared with vitamin D insufficient children from mothers receiving standard dose (400IU/day) [41]. Same study also found that serum 25(OH)D concentration indicate whole body mineralization was higher in vitamin sufficient children at age 6 years, with the greater effect in vitamin D children from mothers receiving high dose of vitamin D. Thus indicating that childhood vitamin D sufficiency improved bone mineralization and in combination with pre-natal high dose vitamin D supplementation reduced the risk of fractures.

V. Conclusion

Randomized clinical trials have demonstrated that vitamin D with or without calcium can increase BMD, decrease bone turnover and subsequently decrease fracture incidence. It is not known whether vitamin D is effective in vitamin D deficient or insufficient older individuals, or in complete older population. The dose response relationship is unclear. Meta-analysis of ongoing studies assessing the effects of higher daily doses of vitamin D on fracture risk are needed before making recommendations on the use of vitamin D for prevention of fractures. Some meta analysis favors the addition of calcium to vitamin D regimen. However further trials are needed to assess the efficacy and safety of higher daily doses of vitamin D with calcium for fracture prevention among older individuals with frailty or among other high risk groups with low vitamin D status. Due to the availability of limited data of the association of vitamin D with osteoporosis, osteomalacia and fracture risk, further exploration is required especially for vitamin D deficient high fracture risk population. Another question that needs to be addressed is whether vitamin D should be prescribed to all elderly or tailored to risk groups. Having said that, the optimal dose may differ between individuals i.e. in case of different genetic polymorphism, chronic diseases and co-medication.

As the amount of research investigating vitamin D needs of children, unfortunately, the answers have become more unclear. Vitamin D deficient rickets is a disease with severe morbidity that responds well to
vitamin D supplementation. Osteomalacia and bone hypomineralization, not of the magnitude of rickets, is more difficult to be diagnosed, therefore study of its response to vitamin D supplementation is challenging. Observational studies in children point to at least 10µg/day vitamin D supplementation to achieve optimal bone health, but results of RCTs have not been clear. Vitamin D have been found to play a significant role in immune function especially in auto immune functions, infections, and allergic disease, but again the trials of its supplementation have little to prove the hypothesis. Due to these study results and other related issues, national and international guidelines are being restructured to reflect this ambiguity and provide less injunction regarding vitamin D supplementation after infancy. Attention to standard 25(OH)D concentration and investigation of genetic or other individual variations in vitamin D metabolism hopefully will identify the cause of these discrepancies in research results.
